ABSTRACT

Breast cancer is a dangerous and it increases the death rate among women cancer detection in early stage is not an easy task. The reason of the cancer is uncontrollable cells growth. In this paper an automatic mammogram classification techniques using symlet wavelet, gabor filter and nearest neighbour algorithm are used for getting better result.

INTRODUCTION

Mammography is a useful method for early breast carcinomas detection [1]. Diagnosis of Breast cancer using xray mammography is very good method. But many studies reveal that radiologists can be done misdetection of abnormalities in addition to having higher rates of false positive. 75% is the estimated sensitivity of radiologist in Breast cancer screening. To avoid this double reading was suggested to be effective to improve sensitivity but it is costly and it takes time to read [2]. Cost effectiveness is important for mass screening programs to succeed. The diagnosis may be affected due to human factor of the abnormality indicators usually varied in shape, size and brightness. Difficult task to find out tumours and ordinary calcification [3,4]. In this paper, an automatic mammogram classification techniques using wavelets, gabor, feature selection is used to know the relationship between the features and classifier used to classify benign and malignant.

METHODOLOGY

MIAS is a digital mammogram database where films from U.K.’s National Breast Screening Programme have been digitized to 50 micron pixel edge with a Joyce-Loebl scanning microdensitometer, a linear device in a 0-3.2 optical density range representing pixels with an 8-bit word [5]. The database includes 322 digitized films and radiologist "truth"-markings on locations of abnormalities detected. The database was reduced to 200 micron pixel edge with padding/clipping to ensure that all images are 1024x1024 pixels at 8 bits per pixel. Erosion followed by dilatation has a similar structuring element, completing the opening function. The MIAS database [6] though no longer supported, is old used much in literature. MIAS annotations are insufficient for some studies as all circumscribed/speculated lesions are to be manually segmented [7]. Another drawback is its digitized resolution which renders it unsuitable for micro-calcification detection experiments. Regarding calcifications, healthier tissue is found in the ground truth region which is justified through calcifications shape as the latter are small lesions spread over a large area with all this being included in the annotation. Cross validation ensures higher formalism in entry data division considered necessary due to limited images with calcifications available in the database. The database Mini MIAS, prevents excessive network training and so a better system generalization.

**ANALYSIS USING MULTI RESOLUTION APPROACH**

Multi resolution is a scaling function. It is used to create a series of approximation of a function or image [8]. Each differing by a factor of 2 in resolution from its nearest neighbour approximation [Gonalez et al 2004]. In this system image scaling is used in order to reduce computing time. The wavelet transform have been used for micro calcification detection using symlet wavelet, a function of a continuous variable into a sequence of coefficient like sequence of number usually called as detail and approximation [9]. The wavelets are functions and those functions are basis for other functions called mother wavelet. The series of function generated by translation and dilation of mother function.

The four different coefficient are produced in each level of decomposition. The decomposition takes place while applying 2D wavelet transform on image. Those are horizontal, vertical, diagonal and approximation coefficient. DWT analysis the image by decomposing into coarse approximation via lowpass filtering and detailed information via highpass filtering. The decomposition is performed recursively on lowpass approximation coefficient at each level until the necessary iteration are reached. Micro calcification appear in the mammogram image as fine and bright grains in the tissue, so the detailed coefficient having micro calcification in the mammogram image using wavelet decomposition. In this research three level discrete wavelet decomposition by using symmetric daubechies of order 2 [10]. The preprocessing time can be reduced using region of interest (ROI). The ROI extraction ignored the dark areas at particular frequency and orientation gabor filter can be viewed as a sinusoidal plane [11]. Symlet wavelet along with gabor filter for detecting mass easily. Gabor filter bank applied in different frequency and orientation on HH high frequency subband image obtained using symlet and extracted statistical features like standard deviation and mean in the form of feature vector.

ROI selected the centers of the abnormality. After getting the feature vector, the feature can be selected using searching method [12]. The number of features obtained after applying the feature selection method [13]. The classifier used to classify the mass into calcification and non-calcification. The classification can be done using Euclidian distance as a measurement between the coefficient [14][15]. In a class, there is a N of images. These images are used to create class core vector and the core vector calculated by...
The Euclidian distance can be calculated by

$$D = \sum_{i=1}^{m} (CCV^i - V_{test}^i)^2$$

It is used to calculate the distance between the tested image and class core vector.

**DISTRIBUTION OF THE MIAS DATA BASE**

In this research MIAS (Mammographic Image Analysis Society) data set is used. This data set was investigated & labeled by the experts. This data set having 322 mammogram image of right and left breast. From 161 patients, 51 diagnosed as malignant, 64 has benign and 207 as normal. This result shown in [Table -1].

**RESULT AND ANALYSIS**

To distinguish between the types of tumors based on the physical properties and level of risk. The six abnormality cases are used as important class. Those are microcalcification, circumscribed masses, ill-defined masses, spiculated lesions, architectural, asymmetry. Next, classifying whether those cases are benign or malignant tumors. The following table shows the classification rate with accuracy based on 10 fold cross validation. In each fold, the average rate calculated and total average of 10 fold can be calculated (Table-1).

CONCLUSION

The diagnosis of breast cancer in a digital mammogram is a practical field of investigation. In this study the concept of using wavelet coefficients and gabor coefficients are used to form future vector and multi resolution analysis used in future extraction. Experiment which applied on real data shows the above results. The accuracy rate of classification achieved to distinguish between bennign ang malignant is 94.09 %. The results shows a special concentration on the wavelet coefficient that gives high percentage of success to find the tumour in each class.
